Viral gastroenteritis

Krisztián Bányai, Mary K Estes, Vito Martella, Umesh D Parashar

Enteric viruses, particularly rotaviruses and noroviruses, are a leading cause of gastroenteritis worldwide. Rotaviruses primarily affect young children, accounting for almost 40% of hospital admissions for diarrhoea and 200 000 deaths worldwide, with the majority of deaths occurring in developing countries. Two vaccines against rotavirus were licensed in 2006 and have been implemented in 95 countries as of April, 2018. Data from eight high-income and middle-income countries showed a 49–89% decline in rotavirus-associated hospital admissions and a 17–55% decline in all-cause gastroenteritis-associated hospital admissions among children younger than 5 years, within 2 years of vaccine introduction. Noroviruses affect people of all ages, and are a leading cause of foodborne disease and outbreaks of gastroenteritis worldwide. Prevention of norovirus infection relies on frequent hand hygiene, limiting contact with people who are infected with the virus, and disinfection of contaminated environmental surfaces. Norovirus vaccine candidates are in clinical trials; whether vaccines will provide durable protection against the range of genetically and antigenically diverse norovirus strains remains unknown. Treatment of viral gastroenteritis is based primarily on replacement of fluid and electrolytes.

Introduction

Acute gastroenteritis is a common illness that affects people of all ages, with potentially severe complications in young children and elderly people who are vulnerable to dehydration. Since their identification in the early 1970s, enteric viruses have been recognised as a leading cause of gastroenteritis worldwide. Of the major enteric viruses, rotaviruses have a predilection for young children, whereas noroviruses affect people of all ages. Viral gastroenteritis manifests abruptly with vomiting and watery diarrhoea, often accompanied by low-grade fever and abdominal cramps. To differentiate viral gastroenteritis from gastroenteritis caused by bacterial agents on the basis of clinical manifestations alone is often difficult, and laboratory tests are required to make a specific diagnosis. Viral gastroenteritis is generally self-limited with recovery within 2–5 days, and treatment efforts focus on maintaining adequate hydration. In this Seminar, we highlight advances in our understanding of viral gastroenteritis and its prevention and control.

Aetiology

Rotavirus

Rotaviruses belong to the Reoviridae family, and are characterised by a 70–75 nm non-enveloped multi-layered virion with 11-segmented double-stranded RNA. Nine rotavirus species have been identified (referred to as rotavirus A to rotavirus I) and a tentative 10th species—rotavirus J—has been described.

Humans are susceptible to infection with rotavirus A, B, C, and H; however, rotavirus A is by far the most medically important species worldwide. The rotavirus genome is approximately 18.5 kb pairs in length, and encodes 11 or 12 proteins, including six structural viral proteins (VP1 to VP4, VP6, and VP7) and five or six non-structural proteins (NSP1 to NSP5 or NSP6). VP7 (G antigen, glycoprotein) and VP4 (P antigen, protease sensitive) are located on the virus surface, functioning as cell-attachment proteins and independently eliciting neutralising antibodies. Genetically, VP7 is classified into G types and VP4 into P types. Rotavirus-type specificities show complex patterns of host-species distribution. In human beings, at least 14 G types and 17 P types of rotavirus A strains have been identified in more than 80 different combinations, but only six combinations (G1P[8], G2P[4], G3P[8], G4P[8], G9P[8], and G12P[8]) account for about 90% of severe infections requiring medical attention. These antigen combinations are expressed on two conserved viral backbone gene constellations—Wa-like and DS1-like. Most strains with G1P[8], G3P[8], G4P[8], G9P[8], and G12P[8] antigen combinations are expressed on the Wa-like genetic backbone, whereas the G2P[4] antigen combination tends to be associated with the DS1-like genetic backbone. However, some studies report an inverse association between the abovementioned backbone gene constellations and their preferably expressed neutralisation-antigen combinations. The sporadic detection of animal (mainly porcine, bovine, canine, feline, and lapine) rotavirus strains in humans suggests that host-specific barriers are permeable to some extent.
In fact, some of the globally or regionally dispersed human strains (including G5, G8, G9, and G12) are thought to have originated from an animal host.8

**Norovirus**

Noroviruses belong to the Caliciviridae family and have a non-enveloped particle, which is 27–40 nm in diameter. The 7.5–7.7 kb positive-stranded RNA genome contains three open reading frames (ORFs); one ORF encodes a polyprotein that is post-translationally cleaved into non-structural proteins (NS1 to NS7), and the other two ORFs have a role in virion formation.9 The major capsid protein, VP1, with two domains (shell S and protruding P) forms the virion with the minor capsid protein VP2. Receptor binding sites are thought to be localised on the P domain. Genetic classification is based on VP1 and the RNA-dependent RNA polymerase (NS7).10 Human noroviruses can be classified into three genogroups and numerous genotypes within each genogroup (ie, nine GI, 22 GII, and one GIV). Further subclassification refers to new variants within a genotype; for example, at least seven variants of the most common norovirus genotype—GI.4—have been identified, all of which emerged after marked antigenic drift, and have caused pandemics over the past two decades with a typical interval of 2–3 years.11 A new globally emerging genotype—GII.17—has been described.12 Further diversification of noroviruses comes from recombination events that lead to new combinations of capsid and RNA-dependent RNA-polymerase types; these norovirus strains with recombinant genomes might have increased fitness and transmissibility over parental strains with shared capsid types.13 Typically, genotype specificity among human and animal noroviruses is not shared, and zoonotic transmission has not yet been firmly shown to occur.

**Other viruses**

In addition to rotaviruses and noroviruses, sapoviruses of the Caliciviridae family (with seven genotypes within genogroup G1, seven within GII, one within GIV, and two within GV), human astroviruses of the Astroviridae family (with eight serotypes, human astrovirus types 1–8), and human enteric adenoviruses of the Adenoviridae family (with two serotypes, HAdV40 and HAdV41) are among the medically important viruses causing gastroenteritis. Together, these agents account for about 10–20% of community diarrhoea cases in children, and are sometimes associated with outbreaks in semiclosed communities in all age groups. Additionally, if patients who are immunocompromised contract any of these viruses, they can develop severe, long-lasting diarrhoea that can occasionally be fatal.14

Depending on the setting and patient population, in up to 50% of acute gastroenteritis cases the causative agent can remain undiagnosed with laboratory methods.15–17 This low diagnostic proportion has prompted efforts towards pathogen discovery using tools such as broad-range PCR assays, pan-viral microarrays, and unbiased viral metagenomics.16 Novel members of the Picornaviridae (eg, salivirus, cosavirus, and Saffold virus), Astroviridae (commonly referred to as VA-like and MLB-like astroviruses), and Parvoviridae families (such as bocaviruses, tusaviruses, and bufaviruses) have been identified in patients with gastroenteritis using these methods. However, similarly to other putative enteric viruses that were identified a long time ago (eg, toroviruses, kobuviruses, and picobirnaviruses), the association between these viruses and gastroenteritis in humans has not been unequivocally confirmed.18

**Disease burden and epidemiology**

**Rotavirus**

In countries without rotavirus vaccination programmes, almost all children have at least one rotavirus infection by age 5 years. Infections in the first 3 months of life are generally milder, probably because of protection from maternal antibodies. Children aged 4–23 months are at greatest risk for severe rotavirus disease, which can include hospital admission. Immunity is incomplete at this age, and repeated infections frequently occur. For example, about 42% of Mexican children who were followed from birth had three or more rotavirus infections by age 2 years.19 However, immunity progressively increases with each subsequent infection, and thus symptoms are milder upon reinfeciton.20 Consequently, although adults can be infected with rotavirus, the disease is usually subclinical or mild.

Rotavirus causes more severe gastroenteritis than most other enteric pathogens. Therefore, the proportion of rotavirus infections that are detected in patients increases with increasing severity of gastroenteritis; these proportions range from 8–10% of diarrhoea episodes of all severity to almost 35–40% of diarrhoea episodes requiring hospital admission worldwide.21,22 Although infection and severe disease from rotavirus are prevalent worldwide, more than 90% of the approximate 200 000 annual deaths from rotavirus globally occur in developing countries, where access to rehydration therapy is poorer than in high-income countries.

Rotavirus gastroenteritis shows prominent winter seasonality in many developed countries, with the prevalence of infection substantially decreasing during summer months.23 In developing countries, however, rotavirus disease is less seasonal than in high-income countries, perhaps reflecting the greater intensity of exposure to rotavirus in these settings.

**Norovirus**

Noroviruses are the leading cause of acute gastroenteritis in people of all ages worldwide, and are estimated to cause 12–24% of community-based or clinic-based cases of acute gastroenteritis, 11–17% of emergency room or hospital cases, and approximately 70 000–200 000 deaths
The incidence of norovirus gastroenteritis is greatest among young children. For example, in a study from England, the incidence of norovirus gastroenteritis was 21.4 episodes per 100 person-years among children younger than 5 years, compared with 3.3 episodes per 100 person-years among those older than 5 years. Notably, in some countries such as the USA and Finland, following the decline in rotavirus disease after rotavirus vaccine implementation, norovirus has emerged as the leading cause of severe paediatric gastroenteritis.

Severe outcomes of norovirus gastroenteritis are also common among adults aged at least 65 years, who account for the majority of fatalities associated with norovirus. Among nursing-home residents in the USA, the number of hospital admissions and deaths from all causes were shown to be significantly elevated during periods with norovirus outbreaks in these facilities, compared with periods without outbreaks. Indeed, in US adults older than 65 years, norovirus is second only to *Clostridioides difficile* as a cause of death from gastroenteritis, with approximately 800 deaths reported annually. Patients who are immunocompromised following a transplant can become chronically infected, and this infection is difficult to clear before restoration of the immune system.

Noroviruses are shed in the faeces of people who are infected, and transmission is faecal–oral, either directly through contaminated hands or by ingestion of food and water that is contaminated with faecal matter. Several characteristics of noroviruses make them highly contagious, including their low infectious dose (around 18–1000 viral particles), the occurrence of viral shedding before the onset of clinical disease in about a third of patients, the extended duration of shedding following clinical illness, the stability of the virus in the environment across a wide range of temperatures (from freezing to 60°C) and their persistence in the environment for days, the absence of complete cross-protection against the range of genetically diverse strains, and the constant evolution of the virus leading to the emergence of new strains.

Noroviruses are the leading cause of outbreaks of acute gastroenteritis, including foodborne outbreaks. In developed countries, outbreak activity tends to increase during the cooler months of the year. Outbreaks are frequently reported in institutional settings such as hospitals, long-term care facilities, and schools because of the close contact among infected individuals. Outbreaks have been associated with food items contaminated with faecal matter at their source, especially consumption of oysters that can concentrate viruses from contaminated waters. However, food contamination often occurs from infected food handlers at the point of service, and ready-to-eat foods such as salads and sandwiches are particularly implicated in this type of transmission. Cyclic increases in norovirus outbreaks occur every few years, and often these increases result from the emergence of genetically distinct viral strains, against which population immunity is inadequate.

Clinical presentation
Clinical presentation of viral gastroenteritis ranges from an asymptomatic infection to severe dehydrating diarrhoea. Asymptomatic viral carriage can be as high as 50% in some populations. In symptomatic infections, the incubation period is 24–72 h. The illness is most typically self-limited with recovery within 2–5 days in individuals who are immunocompetent; in those who are immunocompromised, viral gastroenteritis can last several weeks to months, or even years, irrespectively of the viral cause of infection. Resolution of chronic infection and disease in patients who have undergone a transplant and are immunosuppressed is associated with reconstitution of the immune system and the detection of serum antibodies that can block viral binding to histoblood antigens.

The main features of viral gastroenteritis include non-bloody diarrhoea and vomiting. These symptoms can be accompanied by nausea, abdominal cramps, and fever. Typically, the duration of illness is shorter for a norovirus infection than a rotavirus infection. Nonetheless, viral gastroenteritis is often difficult to differentiate from gastroenteritis caused by enteric bacteria on the basis of clinical presentation alone; therefore, laboratory tests are required for adequate specific diagnosis. Dehydration is a severe complication that can lead to hypovolaemic shock, coma, and death. Disease severity depends on several factors, including viral pathogenicity, as well as the host’s genetics, comorbidities, and immune status. For example, outbreaks caused by GII.4 noroviruses seem to cause more severe illness than those caused by non-GII.4 noroviruses. Additionally, patients who are immunocompromised or elderly develop more severe norovirus disease with greater risk of death. On the contrary, rotavirus infections that are of animal origin can go undetected in children.
because of their reduced virulence, and newborn babies are known to commonly undergo asymptomatic rotavirus infections in neonatal hospital units.\textsuperscript{49,50}

Extraintestinal symptoms, such as respiratory symptoms or central nervous system manifestations in rotavirus infection, or headache, myalgia, and malaise in norovirus infection, are not unusual, but are difficult to interpret without a full understanding of the patient’s immune status, genetics, and comorbidities.

\textbf{Pathogenesis}

\textbf{Rotavirus}

Rotavirus infects intestinal villus enterocytes and enteroendocrine cells; crypt cells are spared. Rotavirus infection-associated diarrhoea is non-inflammatory and involves both malabsorptive and secretory mechanisms. Malabsorption occurs from virus-mediated destruction of absorptive enterocytes, downregulation of the expression of absorptive enzymes, and functional changes in tight junctions between enterocytes that lead to paracellular leakage. A secretory component of rotavirus infection-associated diarrhoea involves elevated intracellular Ca\textsuperscript{2+} concentration, which is important for the stimulation of Cl\textsuperscript{−} secretion.\textsuperscript{52,53} Rotavirus replication in enterocytes and enteroendocrine cells stimulates serotonin release from human enterochromaffin cells, and activates brain regions associated with nausea and vomiting.\textsuperscript{54} Altered plasma-protein function and decreased Na\textsuperscript{+} absorption by inhibition of sodium–hydrogen exchanger activity also contribute to diarrhoea.\textsuperscript{55,56}

A short period of viraemia can occur in a large proportion of children with severe rotavirus gastroenteritis, and virus can be detected in the non-intestinal tissues of those who are immunocompetent.\textsuperscript{57,58} The clinical consequences of systemic infection in children remain unclear, but could explain putative associations with conditions such as a central nervous system disease, meningitis, and biliary atresia.

\textbf{Norovirus}

Information about norovirus pathogenesis, pathology, and immunity has been obtained primarily from volunteer studies, because human noroviruses remained non-cultivatable in intestinal epithelial cells until 2016, and no animal model fully recapitulates human disease after oral inoculation.

Histological changes are present in jejunal biopsy samples.\textsuperscript{59-61} Symptomatic illness correlates with broadening and blunting of intestinal villi, crypt-cell hyperplasia, cytoplasmic vacuolisation, and infiltration of polymorphonuclear and mononuclear cells into the lamina propria, with the mucosa remaining intact. The extent of small intestinal involvement remains unknown. Intestinal biopsy samples from children chronically infected with norovirus after small intestinal transplants show increased enterocyte apoptosis and inflammation that is difficult to distinguish from allograft rejection.\textsuperscript{62} Additionally, human norovirus antigen has been detected in villus enterocytes but not crypt cells of immunocompromised patients with chronic norovirus infection who had undergone haematopoietic-stem-cell or small-bowel transplantation.\textsuperscript{63} Norovirus infection is also associated with epithelial barrier dysfunction.\textsuperscript{64} Although noroviruses exhibit high species specificity, gnotobiotic piglets and calves can be infected orally with GI1.4 human norovirus; once infected, these animals have mild diarrhoea and patchy infection of the intestine, primarily of the proximal small intestine (duodenal and jejunal) enterocytes.\textsuperscript{65}

Experimental human infections show that small-intestinal brush-border enzymatic activities (alkaline phosphatase, sucrase, and trehalase) are decreased, resulting in mild steatorrhoea and transient carbohydrate malabsorption.\textsuperscript{66} Jejunal adenylate cyclase activity is not elevated, and transient gastric secretion of hydrochloric acid, pepsin, and intrinsic factor occurs.\textsuperscript{67} Gastric emptying is delayed and this, or the transient structural damage to the intestinal villi, might contribute to nausea and vomiting.\textsuperscript{68} Symptomatic illness might also be due to the host’s innate immune response to the viral infection, including responses to induced cytokines.\textsuperscript{69}

Further understanding of human norovirus infection and pathogenesis is expected with the successful cultivation of these pathogens in novel human intestinal stem-cell-derived cultures called human intestinal enteroids.\textsuperscript{70} These non-transformed epithelial-cell cultures from different segments of the small intestine are multicellular, and enterocytes in these cultures support the replication of numerous viral strains; replication is strain dependent and replication of individual strains either requires or is dependent on the addition of bile to the cultures. This system can be used to evaluate virus inactivation and measure the amount of neutralising antibodies, and can allow a detailed understanding of virus–host interactions in these physiologically active cultures.

\textbf{Immunity}

\textbf{Rotavirus}

The first level of immunity to human rotaviruses is an innate susceptibility or resistance to infection based partially on an individual’s fucosyltransferase 2 (FUT2) genotype. FUT2 controls fucosylation and the expression of ABH histo-blood group antigens (HBGAs) at the intestinal mucosa. These carbohydrates function as binding ligands and are thought to be the initial receptors required for rotavirus binding to host cells. Susceptibility or resistance to a particular rotavirus strain depends on whether the cell surface in the gut expresses the appropriate binding glycan. Human rotaviruses bind to HBGAs, whereas most animal virus strains bind to sialoglycans. The distribution of HBG type in different human populations affects the prevalence of common rotavirus genotypes across the globe, and susceptibility to some strains of animal origin.\textsuperscript{70-72} Innate immunity
that regulates interferon and the induction of interferon-stimulated genes also has an important role in modulating rotavirus infection in vitro and in animal models, but its role in humans remains to be fully understood.

Additionally, acquired immunity is important to prevent both recurrent disease, and to a lesser extent, reinfection following primary infection. Protection generally positively correlates with markers of mucosal immunity, including concentrations of anti-rotavirus intestinal immunoglobulin (IgA), enteric rotavirus reactive antibody-secreting cells, and IgA memory cells. Studies in mice have shown that B cells act as the primary protection from reinfection, whereas CD8 T cells are responsible for shortening the course of primary infection. CD4 T cells are generally involved in supplying help to CD8 T cells and B cells, and they can also mediate active protection via an interferon-γ-dependent pathway after immunisation with recombinant VP6, the major structural protein in the virus. Lymphocyte homing also has a prominent role in regulating rotavirus immunity, and B-cell trafficking to the intestine seems important to generate optimal protection in a chronically infected mouse model. Neutralising antibody targeting VP4 or VP7 can transfer either homotypic or heterotypic protection. Non-neutralising IgA antibodies targeting VP6 can also mediate protection, apparently via an intracellular antiviral effect that occurs during transcytosis. Viral-induced diarrhoea is reduced in mouse pups born to dams immunised with the enterotoxin NSP4. The role, if any, of these protective mechanisms in human immunity is unknown, and a correlate of protection remains to be established.

**Norovirus**

Immunity to human noroviruses is first based on an innate genetic susceptibility or resistance to infection based on the presence of host HBGAs that serve as cellular attachment factors required to establish infection and clinical disease. Many human noroviruses bind to HBGAs present on the surface of epithelial cells, but noroviruses cannot bind to the cells of individuals in whom these antigens are absent (ie, non-secretors). The absent expression of secretor-type HBGAs on the gut epithelium is associated with resistance to infection with GI.1 and most GII.4 strains. HBGAs bind noroviruses in a strain-specific manner.

The contribution of adaptive immunity to protection began to be understood once genetic resistance was recognised. Serum antibody concentrations measured by ELISA do not reliably predict susceptibility or resistance to illness, because these assays measure antibodies that simply bind to particles. Instead, higher concentrations of pre-existing serum antibody that block viral binding to HBGAs are associated with a decreased risk of illness in individuals who are secretor positive, and who have been exposed to GI.1 or GII.4 virus in epidemiological studies. HBGA-blocking assays are considered to measure functional antibody, which is a surrogate for neutralising antibody and a correlate of immunity. Having the ability to measure functional antibody that correlates with protection facilitates the evaluation of norovirus vaccines. Norovirus infection during adulthood leads to an increase in circulating, virus-specific, IgG-producing and IgA-producing plasmablasts 1 week after infection, and virus-specific memory B-cell concentrations then peak at 2 weeks. Pre-existing serum IgA and IgG and high concentrations of IgG memory B cells at the time of virus exposure are also associated with a lower risk of illness. Maternal antibodies help protect children from norovirus infection, and children subsequently develop antibodies with high blocking activity. Norovirus-blocking antibodies persist for at least 6 months in adults and children. T-cell responses occur after infection, but their relative importance is less well characterised than that of B cells and antibodies. The contribution of past infection with heterologous strains to protection from infection from new strains remains to be fully understood; heterotypic HBGA-blocking responses can be observed in both adults and young children, but some evidence suggests primary infection of children might not result in protection from infection with other strains.

**Laboratory diagnosis**

Routine aetiological testing of patients presenting for treatment of acute gastroenteritis is not required. Testing could help guide specific treatment in patients with severe gastroenteritis, particularly those with bloody stools, illness associated with travel, prolonged illness, or in patients with underlying chronic conditions.

**Rotavirus**

Laboratory diagnosis of rotavirus infection relies on direct viral detection from faecal specimens, which can contain up to 1×10⁹ viral particles per gram of stool. Commercially available enzyme immunoassay tests show high specificity and sensitivity (>90% each), and are the most commonly used assay format in clinical and public health laboratories. Other antigen detection methods, such as latex agglutination and lateral flow immunoassays are available for point-of-care diagnosis. Importantly, detection of rotavirus antigen correlates better with the presence of illness than with the detection of viral nucleic acids (eg, by RT-PCR). When viral nucleic acid detection is used, subclinical infections are also identified.

New-generation molecular detection methods that rely on expensive laboratory equipment and target multiple gastroenteritis pathogens simultaneously show high sensitivity and specificity for rotaviruses (>90% each).
infection. End-point RT-PCR and real-time RT-PCR assays that target the genomic region bridging the RNA polymerase and major capsid protein-coding region are among the most broadly used detection methods. Sequencing of this short amplified region provides information about genotypes that is useful in molecular epidemiological studies.95 Norovirus also serves as a target in multiplexed molecular detection assays.93,94

Antigen-detection assays usually contain a mixture of norovirus-specific antibodies and show some variation in sensitivity because of the large number of antigen types. Rapid antigen-detection tests have been commercialised for point-of-care diagnosis. Additionally, enzyme immunoassays are available and show similar specificity and sensitivity with immunochromatography tests.95 Although the overall sensitivity is low (up to 52% for genogroup G1 norovirus and up to 78% for the prevailing GII.4 noroviruses), in outbreak settings where multiple samples are available for testing, this low sensitivity could be acceptable.

**Treatment**

For treatment of dehydration caused by gastroenteritis viruses, the administration of reduced-osmolality...
oral-rehydration solutions (50–60 mmol/L sodium) is the first line of therapy. Profuse vomiting, worsening dehydration with altered consciousness, or severe acidosis, hypovolemic shock, abdominal distension, and ileus are indications for intravenous rehydration.96 Probiotics (eg, *Lactobacillus rhamnosus* strain GG, *Lactobacillus reuteri*, and *Saccharomyces boulardii*) reduce the duration of diarrhoea and can be considered as an adjunct to rehydration therapy.97 Breastfeeding should continue in infants, and early resumption of feeding after rehydration is recommended. Zinc supplementation is recommended for children younger than 6 months in developing countries, but its value in developed countries, where zinc deficiencies are rare, is unknown.98 Antimotility drugs are not recommended. Antisecretory drugs and some drugs with broad antiviral effects have been shown to reduce the duration of diarrhoea in some studies; however, the data are either non-conclusive or not sufficient to recommend the routine use of these drugs in children.99–102 Additionally, selected antiemetics that reduce vomiting are available but are not universally recommended, because they might increase the frequency of diarrhoea and have other side-effects.

Oral administration of antibody preparations has shown some benefit in patients who have been admitted to hospital with rotavirus and norovirus, including patients who are immunocompromised, but are not routinely used.103–106

**Prevention**

**Rotavirus**

Since 2006, two rotavirus vaccines with similar efficacy and safety have been licensed—a pentavalent bovine–human reassortant vaccine (RotaTeq, Merck, West Point, PA, USA) and a monovalent human vaccine (Rotarix, GlaxoSmithKline Biologicals, Rixensart, Belgium; table 1). As of April, 2018, routine vaccination of infants against rotavirus has been implemented in 95 countries globally (figure 2).109,110 After vaccine implementation, substantial declines in the incidence of severe rotavirus gastroenteritis have been documented in many countries.111,112 For example, data obtained over nearly a decade following vaccine implementation in the USA show delayed, shorter rotavirus seasons with markedly fewer cases compared with the years before the vaccine programme was implemented (figure 3).111 In several countries, reductions in severe gastroenteritis have been documented in children who are unvaccinated, and even older adults, suggesting that vaccination of young infants might be indirectly protecting these groups by reducing rotavirus transmission in the community.114 Most importantly, declines in childhood deaths from diarrhoea have been documented in several countries after rotavirus vaccine introduction, reaffirming the life-saving potential of these vaccines.115,116

Because rotavirus vaccines are orally administered, concerns were raised as to whether factors such as
co-infection with other enteric pathogens, concurrent illnesses, or malnutrition might adversely effect the performance of rotavirus vaccines in developing countries.117 Because of these concerns, global recommendations for rotavirus vaccine use were only issued in 2009, after randomised trials had shown their efficacy in developing countries.118–120 Although rotavirus vaccines showed lower vaccine efficacy in developing countries than developed countries (50–64% vs 85–98%), the burden of disease prevented by vaccination is greater in developing countries, because of the markedly greater baseline incidence of severe rotavirus disease. Initial results from African countries that have implemented routine rotavirus vaccination have reaffirmed the public health value of rotavirus vaccines.121,122

Several high-income and middle-income countries have identified a low risk of intussusception—a form of bowel obstruction—with rotavirus vaccination, which occurs at a rate of about one to five excess cases per 100 000 vaccinated infants.123–126 Because this risk is relatively low compared with the numerous health benefits of vaccination, global-level and country-level policy makers have not recommended any changes to the rotavirus vaccine policy.127

In addition to the two globally licensed vaccines, several vaccines are being developed by emerging-market manufacturers (table 1). An indigenously manufactured rotavirus vaccine was licensed in India in 2014 after showing 56% efficacy in a trial (ROTAVAC, Bharat Biotech, Hyderabad, India).128,129 As of September, 2017, Rotavac has been implemented in nine states in India (Rotasiil, Serum Institute of India, Pune, India).130,131 As of September, 2017, Rotavac was prequalified by WHO, allowing its procurement by UNICEF for global use; Rotasiil is also being reviewed for prequalification by WHO. Additional vaccine candidates, including both live-attenuated and subunit vaccines are being tested (table 2), and the plasmid-based reverse-genetics system offers extended opportunities to design new generations of rotavirus vaccines.132–134

### Norovirus

Limiting contact with infected people during illness and for 1–2 days after illness resolution and frequent handwashing diminishes the transmission of norovirus.135,136 Exclusion from work during illness and for at least 48 h after illness resolution is recommended for individuals with a high propensity to transmit the virus, such as ill staff in health-care facilities, and people involved in food handling. Thorough disinfection of contaminated surfaces with a chlorine bleach solution at a concentration of 1000–5000 ppm (1:50–1:10 dilution of household bleach [5–25%]) or another approved disinfectant decreases the environmental spread of the virus.137–139

The high burden of norovirus gastroenteritis, particularly associated with severe outcomes in both children and elderly people, has led to efforts to develop vaccines for the prevention of endemic norovirus disease. Groups with a high propensity to transmit norovirus, such as food handlers and health-care workers, might also be candidates for a vaccine. Vaccines based on virus-like particles (VLPs) are in phase 2 clinical trials, and vaccines based on recombinant adenoviruses expressing norovirus VP1 protein are in phase 1 clinical trials (table 2).140

Volunteers who were intranasally administered a monovalent GI.1 VLP vaccine and challenged with a homologous strain showed that vaccine efficacy was 47%, and the vaccine reduced the severity of illness compared with a placebo.141 Volunteers who were intramuscularly administered a bivalent GI.1 and GI.4 VLP vaccine,142
with the G1.4 component including a consensus sequence from three different G1.4 variants, showed a reduction in disease severity when subsequently challenged with a G1.4 norovirus strain. Although these results are promising, many key issues require further study, including the understanding of the immune correlates of protection, assessment of the duration of protection from vaccination, and the amount of heterotypic protection against antigenically distinct strains, particularly given the continuing and rapid viral evolution leading to the emergence of novel norovirus strains.

Conclusions

Viral gastroenteritis remains a major public health concern because of its global societal and economic burden. Rotaviruses and noroviruses are the most medically important gastroenteritis viruses in childhood. Additionally, norovirus is commonly implicated in gastroenteritis outbreaks in semiclosed communities, and is the leading foodborne gastroenteritis virus globally. The high disease burden caused by these viruses has led to vaccine development, and after three decades of clinical trials, rotavirus vaccines have become a reality, and are available for use in more than 100 countries worldwide. Norovirus vaccine candidates are in clinical trials, but preliminary data remind us that genetic and antigenic diversity within noroviruses could pose challenges for the development of a norovirus vaccine that will elicit cross-protective clinical immunity.

Contributors

KB and UDP designed this Seminar, and KB, MKE, VM, and UDP wrote and reviewed the manuscript.

Declaration of interests

MKE is named as an inventor on patents related to cloning of the Norwalk virus genome, and has received consultant fees from Takeda Vaccines. KB, VM, and UDP declare no competing interests.

Acknowledgments

KB is supported by public health service grants (AI080656, AI105101, and AI057788) from the National Institutes of Health. VM is supported by a grant from the University of Bari (2017–University of Bari–PRIN 2015). The findings and conclusions in this report are our own and do not necessarily represent the official position of the Centers for Disease Control and Prevention.
